Abstract:

Background: Epstein-Bar virus (EBV) causes infectious mononucleosis in more than 90% of children. Rarely, mononucleosis may lead to malignancy. The aim the current study was to introduce a child with mononucleosis and persistent adenopathy.

Case report: A 4-year-old male patient presented with complaints of fever, shortness of breath and sore throat. He was treated with antibiotics and prednisolone. Normal flora was grown by pharynx and blood cultures. Due to the high clinical suspicion (persistent large lymph nodes), open biopsy of cervical lymph nodes was done after 3 weeks and Non-Hodgkin lymphoma disease was diagnosed in the biopsy.

Conclusions: Atypical presentation should be considered for every child and biopsy is inevitable in larger and persistent lymphadenopathy after 2 weeks. Because of poor prognosis and high mortality rate, early detection of lymphoma is very important.

Key Words: Viruses, Epstein-Bar Virus, Lymphadenopathy, Infectious Mononucleosis

Introduction:

Epstein-Barr virus (EBV) which is responsible for more than 90% of infectious mononucleosis in children and known as human herpesvirus 4 (HHV-4) is one of the eight known human herpes types [1, 2]. The triad of sore throat, fever, and lymphadenopathy are the main symptoms in patients with mononucleosis. Abnormality in size, number or consistency of lymph nodes is defined as lymphadenopathy [3]. Lymphadenitis is the swollen lymph nodes which appear as painful lumps in the neck, armpits or groin. A comprehensive medical and social history as well as the history of drug use should be obtained from all patients for lymphadenopathy evaluation. The presence of an enlarged spleen and swollen inguinal, axillary and cervical lymph nodes is most useful for diagnosis of infectious mononucleosis [1, 2]. EBV is an epidemic herpes virus that spreads on a worldwide scale and infects a large proportion globally. Children are infected at a young age (<6 years old), while in developed countries, more than half of the populations are susceptible to the virus, up to the puberty [2, 4, 5]. Non-Hodgkin's lymphoma (NHL) and Hodgkin's lymphoma (HL) are neoplasms arising from cells of the lymphoid lineage. Lymphoma may also result from a variety of the interaction between multiple genes and environmental factors. EBV has been considered a leading candidate as a trigger for several neoplasms [6, 7]. EBV infection enhances an individual's risk of affecting certain types of fast-growing lymphomas like Burkitt lymphoma and nasopharyngeal cancer [8, 9].

Hodgkin lymphoma and some cases of stomach cancer may be associated with EBV infection. Other more "typical" complications comprise rupture of the spleen and hemorrhage, difficulty in breathing and airway obstruction. In general practice, less than one percent of patients affected with LAP have suffered from malignant disease, especially in pediatrics [2, 10]. An infection which spreads from a nose, eye, skin or eye to the lymph nodes causes lymphadenitis. A thorough physical examination and history, and focused laboratory studies usually exclude life-threatening causes of disease [2]. The most common types of malignancy in patients with infectious mononucleosis are leukemia and lymphoma which are less common causes in healthy children [7, 10]. Hence, we report a child with symptoms similar to infectious mononucleosis and lymphoma.

Case Report:

A 4-year-old boy presented with an acute onset of dyspnea, pharyngitis and fever. He had been admitted earlier to another center. Because of classic triad of fever, adenopathy and exudative pharyngitis, he was treated with antibiotics and corticosteroid. His problem was not resolved at the end of treatment, and he was referred to our center. He was the second child of the family, and there was no history of previous hospitalization. Cervical CT scan indicated multiple adenopathies. He was treated with prednisolone due to the mechanical ventilation for severe airway obstruction (respiratory distress) in ICU. When the clinical conditions were better than initially signs and symptoms, he was discharged from first center after 7 days, and immediately referred to us with persistent cervical lymphadenopathy.

An ENT examination showed that the size of his tonsils was larger than usual compared to other children and enlarged lymph nodes were detected in submandible and posterior cervical.

Vital signs included initially:

BP: 110/75 mmHg, RR: 22/min, PR: 100/min, T: 39°C.

The spleen enlarged to several times larger than its normal size and extended into the abdomen. Other examinations were normal.

In primary lab data:

CBC: WBC:7.8×10³/μl, POLY:50%, LYMPH:40%, MONO:5.5%, PLT:271×10³/μl, BS:101 mg/dl, BUN:11 mg/dl, Cr:0.5 mg/dl, LDH:100 U/L, Uric Acid:2.5 mg/dl, ESR:101 mm/hour, CRP:8 mg/dl, U/A:NL

Chest X-ray was taken and perihilar adenopathy was seen (fig 1). Peripheral blood smear demonstrated hypochromic microcytosis anemia. Normal flora was grown by pharynx and blood cultures in BACTEC medium. He became stable, his fever was discontinued and prednisolone gradually reduced. Real time PCR and VCA IgM was positive for EBV. Abdominal ultrasound revealed multiple lymph nodes and splenomegaly (13 cm). In the next step, abdominal CT scan was performed and for further studies, bone marrow aspiration and biopsy were carried out, which were normal.

Other investigations included HIV test, immune system evaluation, and CH50, which were negative. The abdominal CT scan illustrated the multiple lesions in the terminal ileum with a pattern of inflammatory diseases (fig 2). Although EBV was the cause of the disease, cervical lymph node biopsy was performed. As a result, Hodgkin lymphoma was found and he was treated with chemotherapy.

Discussion:

Concurrent lymphoma and EBV infection was important matter in our case. Unusual reaction to EBV is more common in adults than in children [12]. We introduce this rare presentation in our case report.

In some cases, latent virus may be reactivated. "EBV-associated" cancers are determined by the proliferation of monoclonal EBV-infected cells with limited latent viral gene expression. Disturbance of normal growth control mechanisms within a cell may lead to the uncontrolled cell division and cancer development [6, 13, 14].

Evidence has been suggested that the failure of the EBV-specific immunity may play a role in the pathogenesis of EBV-associated tumors, and manifest the immunodeficiencies in patients. Our patient had normal immune system.

Epskamp et al. reported a 50-year-old man with symptoms of fever, lymphadenopathy and splenomegaly and found that PCR was positive for EBV as well as his pathobiopsy indicated B cell lymphoma [15]. However, our patient had two different characteristics: 1) positive serology and 2) he was a child.

Viral pharyngitis is most common in young children and its incidence decreases with age. Often, it is self-limiting and benign, while in our case, the most severe form of the viral pharyngitis has presented as lymphoma [16].

Two cases of adult patients with Hodgkin's lymphoma and Epstein-Barr virus were evaluated and RNA PCR was positive, too [17]. Of course, our patient's presentations were different: 1) they had a manifestation of disease after chemotherapy, caused by a potential impairment of immunity and 2) it occurred after their puberty.

Although prolonged use of corticosteroid may be associated with an increased risk of malignancy in mononucleosis, it has not been proved in recent studies [16, 18]. Moreover, it seemed unlikely that the use of prednisolone could interfere with the process in our patient during these short times.

In 2012, a 15-year-old teenager with Crohn's disease had extensive lymphadenopathies and type B lymphoma [19]. The Epstein-Barr viral load with active disease was found in our case because he was immunocompetent. It is important to say that the virus can also cause lymphoma, in healthy children.

The history may be diagnostic and suggestive cause of lymphadenopathy; thus, the physician should determine whether the lymphadenopathy is evaluated

or not. It is important to know when the patient is referred to general surgeons for diagnostic lymph node biopsy. Generally, sampling is not recommended before 2 weeks. In cases of treatment failure after 2 weeks or persistent size after 4 weeks in referred patients with cervical lymphadenopathy, the excisional biopsy should be considered [1, 4, 5].

In general, EBV is at higher risk for lymphoma in individuals who have compromised immune systems, specific race and older age.

Therefore, although the manifestations of viruses are often very benign and self-limited in childhood, the unusual manifestations in each child should be considered in approach to lymphadenopathy. Early diagnosis because of the mortality reduction and better prognosis is very important [7, 20].

In conclusion, early diagnosis of lymphoma in our immunocompetent patient was very noticeable, because EBV might be malignant in immunocompromised persons. Atypical presentation should be considered for every child and biopsy is inevitable in larger and persistent lymphadenopathy after 2 weeks. Because of poor prognosis and high mortality rate, early detection of lymphoma is very important.
